This bulletin contains information concerning the costs of fattening beef cattle in five representative feeding districts of the Corn Belt and shows the influence of different methods and practices upon costs and returns. The study was begun in the fall of 1918 and was continued during five consecutive feeding seasons. The districts chosen for study were located in eastern Nebraska, southwestern Iowa, west-central Missouri, northern Illinois, and various counties of central and northern Indiana. Each season approximately 100 records of feeding operations were obtained from farmers in each of these districts. An effort was made to obtain all the details of management from the time the feeder cattle were bought until the fat cattle were marketed. The effect of the kind and quantity of feed available upon methods of handling and rations used was

given special attention. The location of the districts studied and the territory to which the data on cattle feeding apply are shown in Figure 5.

IMPORTANCE OF THE CATTLE-FATTENING INDUSTRY

Farm roughages and feed grains in the Corn Belt are marketed chiefly through the fattening of cattle. Over 25 per cent of the corn produced in this area is fed to beef cattle. Beef cattle are well adapted to the utilization of coarse roughages and legume hay, which must have a place in a well-balanced crop rotation. These roughages when fed with corn in the ration produce a higher grade of beef than that which is produced on grass alone.

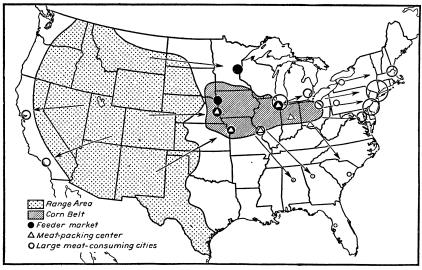

FIG. 1.-MOVEMENT OF BEEF FROM THE RANGE

The steps in beef production are as follows: (1) Growing stockers, feeders, and grass-fat cattle on the range; (2) fattening stockers and feeders in the Corn Belt feed lots; (3) slaughter, packing, and delivery to retail dealers by packers; and (4) retailing to consumer.

Both geographically and economically the Corn Belt is located between the range beef-producing area and the eastern beef-con-

suming cities. (Fig. 1.)

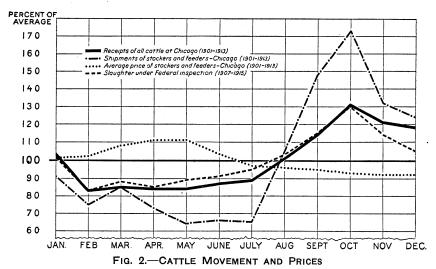

Probably three-fourths of the beef cattle sold from the range are marketed during the last five months of the year. About one-third of them are usually shipped out to the feed lots of the Corn Belt as stockers and feeders. The marked seasonal variations in the recipts of all cattle, the shipments of stockers and feeders, and the price of feeder cattle are shown in Figure 2. Besides improving the quality and condition of a large number of cattle from the range, the fattening of steers in the Corn Belt tends to equalize the number of cattle slaughtered at different times of the year.

The high value of Corn Belt land for crop purposes has led many farmers to the conclusion that they can not afford to use tillable pasture land to keep a breeding herd of beef cattle to raise calves. Instead they make a practice of buying feeder steers from western ranch-

men and from farmers in the vicinity who have cheaper pasture. Only a few of the cattle included in this study were raised by the same men who fattened them. A large part of the purchased steers came

originally from the range States or from Canada.

There is a tendency to market cattle from the range at a younger age and at a lighter weight than formerly. As this tendency becomes more marked, the fattening of beef cattle in the Corn Belt may be expected to become increasingly important because the younger cattle do not fatten so well on the range as do the steers over 2 years of age. If the Corn Belt land is to produce the necessary corn and roughage to finish these steers it will mean using more tillable land for grain and hay production and less for pasturing cows to raise calves. There are possibilities of raising beef calves economically on tillable Corn Belt

The purchase of stocker and feeder cattle in the fall tends to equalize the number of cattle slaughtered throughout the year.

land by increasing the carrying capacity of pastures by the use of clovers and other legumes, but the fattening of beef cattle that have been purchased from the ranges as feeders will continue to be a very important enterprise in the Corn Belt.

PURPOSES OF THE STUDY

The principal purposes of this study of cattle feeding were: (1) To determine from the operations on a large number of farms the quantities of feed, labor, and other cost factors involved in fattening cattle of various ages and weights; (2) to analyze the feed-lot performance of cattle of various ages and weights with respect to rate of gain, length of time fed, and the ability to utilize different kinds of feed; (3) to determine the spread in buying and selling prices or margins necessary to meet the cost of feeding cattle of different weights for different lengths of time with varying prices of feed and of cattle; (4) to find the cost of production and to study the variations in costs with a view to determining the most profitable feeding methods and practices to follow under different price levels in different sections of the Corn

Belt; and (5) from the results of feeding operations during the time of this study to present information that will aid the cattle feeder in planning and following the most profitable methods in cattle feeding.

DEFINITION OF TERMS AND METHODS OF COMPUTATION

For those who may be interested in making a more detailed study of the figures in the tables of this bulletin it was thought advisable to define the terms used more fully than has been done thus far and to show just how the figures were derived.

Initial weight of cattle is the market weight at time of purchase or the estimated weight at the farm at the beginning of the period

covered by the record.

The number or percentage of cattle applies to those sold unless

otherwise specified.

The weight classes of feeder cattle have been defined in the text. The year 1919, sometimes called 1918-19, designates the feeding season beginning during the fall of 1918 and extending through the

following summer.

In nearly all instances averages are computed from total figures rather than by averaging averages. For instance, in Table 6 the average initial weight of cattle in Nebraska for the five years was obtained by dividing the total weight of all cattle by the total number of cattle.

Total weight \div 17,162 = 826.

The average quantity of grain used in making 100 pounds of gain during the five years in Nebraska (817 pounds) was obtained by dividing the total quantity of grain used by the total gain made by the 17,162 head fed.

Methods of handling cattle, such as strictly dry-lot feeding and

fattening on grass, are defined in text.

The final weight per head is the average weight of the cattle that were sold and of those that died, or, in other words, the sum of the weights of the cattle sold and of those that died divided by the total number of cattle bought.

Gain per head is the difference between the initial weight per

head and the final weight per head.

The number of days on farm is that length of time between the average date of arrival and the average date out of the lot of all cattle, including also the cattle that died.

The average daily gain per head is obtained by dividing the total gain on cattle sold and on those that died by the total days on the

farm.

In some places days on feed have been used to designate the length

of time on grain feed.

Grain is practically entirely corn but also includes other cereal crops, especially oats and barley.

Protein concentrates include linseed meal and cottonseed meal. Prepared feeds are manufactured feeds in which varying proportions of alfalfa, oat hulls, cottonseed meal, molasses, and other feeds are usually combined.

Legume hay includes, besides clover and alfalfa, a very small quan-

tity of cowpea and soy-bean hay.

Other hay means wild hay, timothy, millet, or Sudan-grass hay. Corn stover is fodder from which the corn has been removed.

The number of pasture days is that length of time during which cattle obtained a significant proportion of their feed from grazing.

Pork credit is the number of pounds or value of gain in live weight of hogs following the cattle. This was credited to the cattle after allowing for gains due to extra feed given to the hogs.

Manure is another feed-lot by-product credited to the cattle-feed-

ing enterprise.

All feed prices used are the farm prices for those feeds, except that silage is charged to cattle at the farm price of corn plus the cost of putting it in the silo.

The initial cost of the cattle and the sale price per 100 pounds of

cattle and hogs are on a farm-price basis.

The margin received is the difference between the initial cost and

the sale price per 100 pounds.

The necessary margin is that amount at which cattle must sell above the initial cost per 100 pounds to pay all charges for feed, labor, depreciation, and other items. (Net cost per head divided by sale weight per head minus initial cost per 100 pounds.)

The feed cost per 100 pounds gain is computed by dividing the total feed cost for the group by the total number of pounds gained

by cattle that were sold and by those that died.

Feed cost per head is obtained by dividing the total feed cost by

the number of head sold.

Return per bushel of corn fed is the value of the corn fed at the farm price of corn plus or minus the profit or loss per head divided by the number of bushels of corn fed.

The sale price per 100 pounds is the sale price per head divided by

the final weight.

ECONOMIC CONDITIONS AFFECTING CATTLE FEEDING DURING THE PERIOD STUDIED

In the fall of 1918, when this study was begun, prices of all commodities were abnormally high, because of the unusual conditions of the war period. Figures 3 and 4, by the use of price indices, show the relation of feed prices to the prices of beef cattle, hogs, and all commodities. Considering the prices which existed from 1909 to 1913, inclusive, as a base, or 100, the price index of all commodities for the period of high prices, including the two years 1918 and 1919, was about 205 per cent of the pre-war average, that of beef cattle about 210, that of hogs 227, that of corn 270, and that of linseed meal 175. Thus the price of corn during the first two years of the study was considerably higher than the average price of all commodities, while the price of linseed meal remained relatively lower than that of other things. The index numbers of prices of hogs and of beef cattle were slightly higher than the index number of wholesale prices of all commodities during this period.

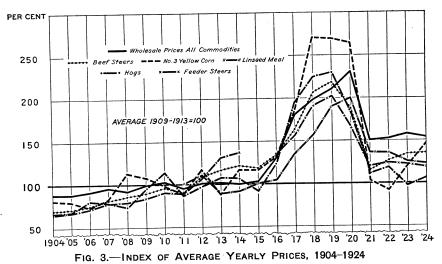

The wholesale prices of most products started downward in June, 1920. The price index of all commodities ¹ fell from a peak of 252 in

¹ This index number is derived from the monthly index number published by the Bureau of Labor Statistics. The figures as published are on a 1913 base, but have been converted to a five-year base, 1909–1913, by dividing by 0.98. See United States Department of Labor, Bureau of Labor Statistics. Index Numbers of wholesale prices in The United States and Foreign countries. U.S. Dept. Labor, Bur. Labor Statis. Bul. 284, 350 p., illus. 1921. (Revision of Bul. 173.)

May, 1920, to 148 in May, 1921. Prices of agricultural products did not begin to dip downward until September, 1920. The price index of beef cattle dropped from 212 in September, 1920, to 116 in May, 1921, while the index of hog prices fell from 205 to 108, that of corn from 217 to 100, that of linseed meal from 175 to 106, that of cotton-seed meal from 196 to 111 per cent of the pre-war average in the

same period of time.

Unemployment in this country in 1921 and a weak foreign market situation caused by unemployment and depreciated currency abroad lessened the demand for beef and pork so that by December, 1921, the indices of the prices of these products dropped to 98 and 90, respectively. Record-breaking crops of corn in 1920 and 1921 caused a surplus which pushed down the corn price to a figure which in December, 1921, was only 78 per cent of its pre-war average. Improved industrial conditions in 1922 strengthened the prices of all agricultural

The price of corn was much higher than the price of other things from 1918 to 1920. After 1921 the prices of cattle, corn, and hogs were all below the general price level.

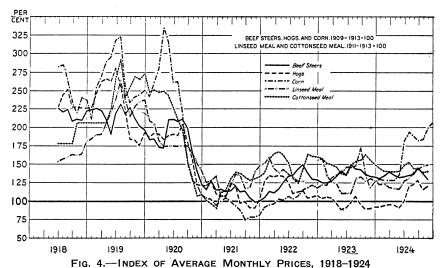

products. Higher prices for hogs in 1922, together with the surplus of corn from the two preceding years, caused an expansion of the hog enterprise which brought the price of hogs to its lowest point in eight years. During the last half of 1923 and the first half of 1924 the price of hogs was only 92 per cent of the 1909–1913 average. Beefcattle prices improved steadily in 1922 and 1923, but in competition with cheap pork in 1924 they fell off noticeably.

Drought in the range area in 1918 and 1919, together with the high prices that had prevailed since the beginning of the war, explain the large market receipts of beef cattle in those years. These two years were the only ones in which over 5,000,000 stockers and feeders were shipped annually to Corn Belt feed lots for fattening. The low prices for beef cattle in 1921 kept a large number from being marketed during that year. The cattle that were held on farms and ranges in 1921 on account of low prices helped to increase the receipts in 1922 and 1923 almost to the high point reached in 1918. In 1922 there was

a drought over a large part of the southwest range area which caused a large number of cattle to be marketed at lighter weights than is

customary.

The price situation that existed while this study was being made created an opportunity to learn which feeding methods were the best to use at different price levels. The five years of this study divide naturally into three periods: One of high price levels, one of low price levels, and an intermediate year when deflation took place. The period of high prices includes the feeding seasons of 1918–19 and 1919–20; the period of low prices includes the seasons of 1921–22 and 1922–23. In the feeding year 1920–21 cattle were bought on a high price level and were sold in the spring at a figure which was but little above the 1909–1913 average. In this bulletin the analysis and discussion

Relations between the prices of feed, beef cattle, and hogs that existed during the study.

of feeding operations will be treated separately for each period because there was too great a difference in prices to make it desirable to average the years.

DISTRICTS STUDIED AND KINDS OF CATTLE FED

Most of the cattle that are fattened with grain are fed in the western half of the Corn Belt, as this is a surplus corn-producing area located at a considerable distance from market. (Fig. 5.) The extent of cattle feeding in the several parts of the Corn Belt depends upon the farm price of corn as compared with farm prices of corn in other parts of the Corn Belt and upon the quantity and kind of roughage available. These factors, together with the amount of pasture available, the age and quality of cattle fed, and the time of purchase, largely determine the method of handling feeder cattle in the Corn Belt.

the method of handling feeder cattle in the Corn Belt.

Cattle feeding may be said to fall into two distinct systems of handling: (1) Fattening in dry lot and (2) fattening on grass. For the purpose of study and comparison the cattle under observation

in this study that were fattened in dry lot have been subdivided into three groups: (1) Cattle that were fattened strictly in dry lot; (2) cattle that were pastured during the fall previous to being fattened in the dry lot; and (3) cattle that were summer-pastured and later finished in dry lot. A typical cattle-feeding layout is shown in Plate 1, Figure 1. Most of the cattle fattened on grass were bought during the fall and carried through the winter previous to fattening, but about one-fifth of the cattle fattened on grass were purchased during the spring at, or just previous to, the time the grass was ready for pasturing.

The percentages of cattle of various weights that were bought each year are given in Table 1. Medium-weight feeders, weighing between

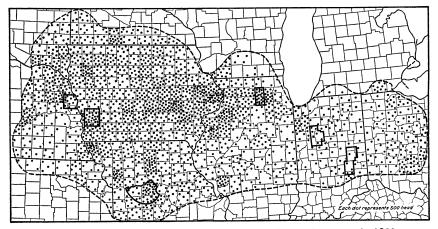

FIG. 5.—NUMBER OF 2-YEAR-OLD STEERS ON FARMS JANUARY 1, 1920

Most beef steers are fattened in the western part of the Corn Belt. The districts where the studies reported in this bulletin were carried on are outlined in each State.

750 and 1,000 pounds when purchased, made up 53 per cent of all the cattle of the study. Feeder cattle weighing between 500 and 750 pounds, called yearlings in this bulletin, were the next largest group.

Table 1.—Initial weight of cattle—Percentage of cattle in various weight classes, by years

FIG. 1.- A TYPICAL CORN-BELT FEED LOT

FIG. 2.—A PERMANENT TYPE OF SILO USED FOR CATTLE FEEDING

All cattle that weighed less than 500 pounds when bought are termed calves in this bulletin and all that weighed more than 1,000 pounds at the beginning of the feeding period are called heavy cattle. A slightly larger percentage of calves and yearlings was fed on the farms under study during the first two years, whereas a distinctly larger percentage of heavy cattle was fed during the last three years. The Nebraska farmers bought the largest percentage of heavy cattle, Indiana and Iowa farmers fed the largest percentage of calves, and Illinois and Missouri farmers had the largest percentage of cattle in the medium-weight group, as shown in Table 2.

Table 2.—Initial weight of cattle.—Percentage of cattle in various weight classes, by districts

EASTERN NEBRASKA

The district in which cattle-feeding records were taken in eastern Nebraska is located just west of the Missouri River, midway between Sioux City, Iowa, and Omaha, Nebr. It includes parts of Burt, Dodge, and Cuming Counties. The land is level to rolling and, according to the census figures, 93 per cent of it is improved land. Corn, oats, wheat, and alfalfa are the principal crops, and hogs and cattle are the most important kinds of livestock. With the exception of wheat, practically all the crops produced there are fed to livestock. The farms of the district average about 186 acres in size, of which about 65 acres are in corn. The average yield of corn for the four years 1919 to 1922 was 40 bushels per acre.

Almost all the cattle to be fattened in this district are bought at the Omaha livestock market between August and December, inclusive. (Table 3 and fig. 6.) The average length of time the cattle spent on the farm during the five years studied was 170 days. The fat cattle are usually sold in Omaha, although about 13 per cent of the cattle in this study were shipped to Chicago. (Table 4.) The steers included in this study that were fed in this district were of better quality than those in any other district studied. A greater percentage of feeders that weighed over 1,000 pounds was fed in Nebraska than was common in the other States, the usual practice being to buy these heavy feeders in September and sell them in December or January. The bulk of the fed cattle are marketed during the period from February to May. Corn and alfalfa hay is the standard ration. There are very few silos in the district, and because of the large amount of alfalfa that is available very little linseed meal or cotton-seed meal is bought. Fifty-nine per cent of the cattle were fattened in dry lot without any pasture, 34 per cent were pastured during

the fall on grass or cornstalks, and 6 per cent were pastured during the summer previous to being fattened in the dry lot. (Table 5.) This eastern Nebraska district is probably as well adapted to the winter fattening of beef cattle as is any section of the Corn Belt.

Most feeder cattle are purchased during the fall, and the fat cattle are sold during the winter and spring.

SOUTHWESTERN IOWA

The Iowa district chosen for study consists of parts of Pottawattamie and Shelby Counties and is located south and east of the Nebraska district on the opposite side of the Missouri River. The land is rather rolling, although practically all of it can be cultivated. About 37 per cent of the total farm area is usually devoted to corn, which yields about 43 bushels per acre. Wheat, oats, and hay are the other principal crops. Alfalfa and sweet clover grow very abundantly in the western half of Pottawattamie County. In the eastern half of the county more red clover and mixed hay are raised. The farm organization is similar to that found in the Nebraska district. The farms are usually quarter sections. As a rule all of the crops except wheat are marketed through livestock.

The principal cattle ration consists of corn and a legume hay, usually alfalfa. There are more silos than in the Nebraska district, but silage makes up a relatively unimportant part of the ration. Only 17 per cent of the cattle in the survey were fed silage. Very little protein concentrate is bought for cattle in this district. Some molasses and molasses feeds were fed during the last two years of the study. Ninety-three per cent of all the cattle bought were fattened in the dry lot; about 46 per cent had no grass, and 47 per cent were pastured during the fall or summer previous to being finished in the dry lot. Only the remaining 7 per cent were fattened on grass.

Almost all the feeder cattle in this district come from the western and southwestern range States, for there are comparatively few beef cows in this locality. The Omaha livestock market furnishes a majority of the feeder cattle. (Table 3.) As shown in Table 4,

58 per cent of the fat cattle in this study were shipped back to Omaha and 36 per cent went to Chicago. The month in which the largest number of feeder steers was bought during the five years was October, and the largest percentage was sold in the month of May. The average length of time on the farm was 182 days, varying from 135 days for the heavy cattle to 220 days for the calves. The average weight of cattle fed was slightly less than that of the cattle of any of the other four districts. The quality of cattle fed in this district was above the average quality of cattle fattened in the Corn Belt.

NORTHEASTERN ILLINOIS

The district studied in Illinois is in De Kalb County, in the northeastern part of the State and about 60 miles west of Chicago. slightly rolling land found in this district is usually divided into farms of 160 acres and is almost entirely tillable. Aside from feeding cattle, dairying is the most important enterprise. Corn is the principal crop, and oats, wheat, barley, and hay rank next in importance. Corn makes a good yield, the average having been 45 bushels per acre during four years of this study. Most farms in the county have one or more silos, and about 15 per cent of the corn was cut for silage. Silos are usually of concrete, brick, or other permanent type of construction. In contrast to the practice over a rather large area south and east of this county little corn was marketed as grain. About 70 per cent of the hay produced in De Kalb County was mixed hay (clover and timothy), 21 per cent was timothy alone, and only 3 per cent of the total hay acreage was in alfalfa. High yields of alfalfa were obtained on some farms, but to get a good stand of alfalfa in this district requires more attention than is needed in some other parts of the Corn Belt, such as western Iowa and eastern Nebraska.

Inasmuch as little permanent pasture was available on the farms under study, 98 per cent of the feeder cattle handled were finished in dry lot. About one-half of this number received no grass; the other half had been pastured on cornstalks, second-growth clover, or other forage during the fall or summer previous to being finished in dry lot. The principal ration used in fattening the cattle consisted of corn, silage, mixed hay, and protein meal. Eighty-five per cent of the cattle received silage and 56 per cent were given a protein concentrate in the ration. (Table 9.) The principal market from which feeder cattle were brought to this area was South St. Paul, which in turn drew its feeders from Minnesota, the Dakotas, Montana, and The Chicago market, because of its proximity, furnished some of the feeder cattle and received practically all the shipments of fat cattle. October and November are the principal months in which feeders are bought, and the largest percentage of them are sold the (Fig. 6.) Sixty per cent of the purchased feeder cattle weighed between 750 and 1,000 pounds each. They were usually in thinner condition and of poorer quality than the feeder cattle bought in any of the other districts studied, with the possible exception of the Missouri district.

CENTRAL INDIANA

The cattle-feeding districts in which records were taken in Indiana are shown in Figure 5. The farms in these districts average somewhat smaller in size than those in the other districts described thus far. As in the other States, corn is the most important crop. The average

yield of corn is usually between 40 and 45 bushels per acre. Wheat is an important cash crop, and oats have an important place in the rotation. Hay is a more uncertain crop than it is in any of the other districts studied. Only a little alfalfa is grown, and clover is not so sure a crop as in some other parts of the Corn Belt. Most of the hay is mixed clover and timothy, 25 per cent is timothy alone, and 18 per cent is clover alone. Silos are almost as common in these sections as in northern Illinois, and in some parts a considerable quantity of corn is fed in the form of fodder to provide sufficient roughage for the cattle.

Eighty-one per cent of the Indiana cattle in this study received some silage, and 50 per cent were fed nonlegume hay, straw, or stover as the principal dry roughage. Forty-three per cent of the droves had a ration supplemented by a protein concentrate. Most of the feeder cattle were bought in October and November, and the fat cattle were sold largely in April and May of the following year. Chicago, Indianapolis, and Kansas City are the most important live-stock markets in which feeders were bought for this district. Fat cattle are usually shipped from this district to Indianapolis, although about one-fourth of the cattle in this study were sold in Chicago. Ninety-two per cent of the cattle were fattened in dry lot; about half of them had pasture during the fall and summer previous. The other 8 per cent were fattened with corn while on grass during the summer. Cattle feeding is a major enterprise on many farms in Indiana, but fewer steers are bought for feeding purposes in this State than in the western half of the Corn Belt.

WEST-CENTRAL MISSOURI

The Missouri district chosen for study extends from 60 to 90 miles east of Kansas City, just south of the Missouri River. It consists principally of parts of Saline, Lafayette, and Pettis Counties. Eighty-seven per cent of the land in farms in these three counties is improved land, according to the census figures of 1920. The average size of farm was 138 acres, and the average value of land and buildings in 1920 was \$149 per acre. About one-third of the improved land is usually planted to corn, and an equal acreage is in pasture. is another important crop, occupying 27 per cent of the improved land in farms. Oats and hay are less important. The tendency since the World War has been to decrease the acreage of wheat, partly because wheat has been none too profitable to the district and partly because it has been difficult to control losses from chinch bugs in corn that is grown where wheat had been grown extensively The average yield of corn for these three counties is about 34 bushels per acre. As it has corn and grass in such abundance, it is evident that this district is well adapted to the production of beef During some seasons considerable additional corn is shipped in for feeding purposes.

The fact that about one-third of the farm acreage is in grass pasture is an important element in determining the method of handling feeder cattle in this district. Most of the feeder cattle under study were bought during October and November, carried through the winter on corn fodder, silage, and hay, and then fattened on corn and grass the following summer. Only 11 per cent of the cattle were fattened in dry lot without any pasture, whereas almost 60 per cent were fat-

tened while on grass. The remainder were pastured before they were finished in dry lot. More silage was fed to steers in this district than in either the Nebraska or Iowa districts but not so much as was fed in Illinois and Indiana. In the last two years of this study many silos were left unfilled. Forty-three per cent of the cattle finished in dry lot received silage. (Table 9.) About 28 per cent were given a protein concentrate as a supplement to corn. Considerable molasses and molasses feeds were also used in the ration. About one-half of the

hay fed to cattle was clover or alfalfa.

Of the cattle that were fattened on grass, 83 per cent were carried through the winter and 17 per cent were purchased in the spring at about the time grass was ready for pasturing. Sixty-five per cent of the cattle which were carried through the winter received corn all the time while on pasture, 18 per cent received little or no corn while on pasture, and 17 per cent were fed corn during the last few weeks before they were sold. The largest number of fat steers were sold in Of those marketed later than that date many were fed until September or October. The average length of time spent on the farm in this district was 224 days, or almost two months longer than the length of time spent on the farm in any other district studied. The Kansas City market is the source of a large proportion of the feeder cattle shipped into western Missouri, although a considerable number are driven in from southern Missouri and northern Arkansas. Those driven in are often 3 or 4 years old and usually of a less desirable type than those bought at Kansas City. Of the fat cattle sold, 41 per cent were shipped to St. Louis, 28 per cent to Kansas City, and 15 per cent to Chicago. The other 16 per cent were sold locally to buyers, who probably shipped to these markets in similar proportions. (Tables 3 and 4.)

BASIC REQUIREMENTS AND COSTS OF FATTENING BEEF CATTLE

The kinds of feed available in a district determine to a large extent the kind of rations which are commonly used in feeding cattle in that district. The prices of these feeds largely determine the proportions in which they are fed at any stated time. The way in which these two factors influenced the rations fed in the different districts during the five years of this study is shown in Table 6 by the quantities of

feed required to make 100 pounds of gain.

In the Nebraska and Iowa districts, where alfalfa is plentiful, more of this hay was used in making 100 pounds of gain than in the other districts. Largely on account of this fact, fewer pounds of protein concentrates and less silage, corn stover, and straw were fed in the Iowa and Nebraska districts than in the other districts. Cattle feeders in the Illinois and Indiana districts, where less legume hay was available than in Nebraska and Iowa, fed more mixed hay, timothy, corn stover, and straw and decidedly more protein concentrates in fattening their cattle. About one-fourth of the corn given to cattle in the Illinois and Indiana districts was fed in the form of silage. In the Nebraska and Iowa districts practically all of the corn was fed as grain.

The relative adaptability of each district to the growing of legume hay is an important reason for these differences in feeding. Another reason is the greater danger of frost damage to corn in northern Illinois than in the other districts studied. Ordinarily, corn is some-

what higher in price in Illinois and Indiana than in the western part of the Corn Belt, because these States are nearer to the Chicago grain market and eastern cities. This price would explain the feeding of larger quantities of silage there than is common in districts where corn is somewhat lower in price. The cattle fed in Indiana did not receive quite as large a proportion of silage as those of the Illinois district, but the quantity of nonlegume hay, straw, and corn stover used in making 100 pounds of gain was larger there than in any other district studied. The average feed requirements for 100 pounds of gain on the Missouri cattle, as shown in Table 6, suggest the cattle-feeding methods practiced and rations used in that district. use of grass pasture is much more important there than in any of the other four States. Considerable quantities of protein concentrates and prepared feeds are usually fed to cattle in this district, and in wintering cattle to be fattened on grass, a common practice in this region, considerable quantities of corn stover and silage are used.

¹ Used for convenience instead of gain in live weight of hogs following the cattle.
² The feeding season 1919 signifies the winter of 1918-19.

The quantity of pork ² produced with each 100 pounds of gain on steers was smallest in the case of the cattle fed in the Illinois district, where silage made up a large part of the ration. The quantity of pork varied almost directly with the amount of corn fed as grain, except in the districts of Indiana, where a large proportion of bundle corn, especially in the last two feeding seasons of the study, increased considerably the quantity of pork produced with each 100 pounds of beef. The quantity of manure produced as a by-product in cattle feeding was greatest in the Illinois and Indiana districts, where the most silage was fed. The man and horse labor requirements for each unit of gain were also greatest where silage was fed most extensively. The average daily gain per steer was highest in Nebraska and Iowa and lowest in Missouri. (Table 19.)

The farm prices of the feeds used by the cattle under study in each State during the five years and the farm prices of the cattle and hogs are shown in Table 7. The farm price of corn tended to be lower in

² This expression is used for convenience. More exactly it stands for the gain in live weight of the hog following the cattle attributable to the feed undigested or missed by the cattle.

the Nebraska and Iowa districts than in those in Illinois and Indiana, and Missouri had the highest priced corn of all the districts during each of the five years of the study. This higher price of corn in the Missouri district is partly due to the seasonal advance in the price of corn during the summer, when a large part of the corn is fed to cattle, and partly to the fact that this is not a surplus corn-producing district. The variations in the price of protein concentrates from one district to another are due principally to the differences in analysis or grade. The price of all farm-grown feeds, except silage, is based on the local market price minus the cost of hauling, whereas the cost of hauling to the farm was added to the amount paid for commercial feeds. In some districts the local price was often as high as the market price because of local competition among cattle feeders for corn and hay. This was true more often in Iowa, Nebraska, and Missouri than elsewhere, and explains the price variation from district to district, especially the variation in the price of hay. The price assigned to silage in the winter of 1918-19 was the farmers' estimate of its value in the silo. For the last four years the cost of filling the silo on each farm was added to the value of corn in the field and then divided by the number of tons in the silo, to obtain the rate at which silage should be charged to cattle.

¹ Details of initial cost of cattle by weight classes, districts, and years are shown in Tables 27, 28, and 29. ² A load was approximately 1 ton.

The purchase price of feeder cattle is the cost delivered at the farm, and the sale price of the fat steers is the net sale price at the farm obtained by subtracting any marketing expenses from the gross returns. The cattle which were fed in the Illinois and Missouri districts had the lowest initial cost per 100 pounds delivered at the farm. This suggests that they were cattle of lower quality than those fed in the other districts. The Indiana cattle generally cost about as much or a little more than those fed in Nebraska and Iowa, but a larger proportion of the original cost per 100 pounds is made up of shipping expense, because Indiana is farther from the supply of feeder cattle.

The average weight of feeder cattle bought was greatest in the fall of 1920 in most districts. In the Indiana district heavier steers were purchased during the following year. The cattle that averaged the lightest in weight of any bought during the five years were fed in 1918–19. The lighter average weight of cattle fed during the first two years of the study was doubtless due in part to drought conditions. The demand during the World War for lighter cuts of beef may have had some effect on the weight of steers purchased for feeding purposes in 1918. In the fall of 1920 large numbers of the young cattle were held on the range in the hope of better prices the next year. This probably accounts for the greater weight of feeder cattle in the Corn Belt feed lots in 1920–21.

The wide variation in the prices of feed during the five years was responsible for most of the differences in the proportionate quantities

of different feeds required to make 100 pounds of gain from year to For instance, the quantity of corn which was used in making 100 pounds of beef during the first two years was much less in all districts than the quantity used during the next two years. Protein concentrates, which were relatively cheaper than corn in 1918 and 1919, were fed more liberally in those years than when the relation of the price of corn to the price of protein concentrates was reversed in the later years of the study. Larger quantities of molasses and prepared feeds were substituted for corn in the first two and in the last feeding seasons than in 1920-21 and 1921-22. A slightly larger proportion of dry roughage and considerably more silage was fed when corn was high in price than during the period of cheap corn.

In the Illinois and Indiana districts about one-third less silage was used for each 100 pounds of beef produced when corn was worth about 50 cents per bushel than when it was valued at \$1.50 per bushel. This situation is perhaps best explained by the fact that the expenses of filling the silo, other than the value of the corn itself, make up a larger percentage of the total cost of silage when corn is cheap than when it is high in price. In the fall of 1921 when corn was valued at 33 cents per bushel in the field, the silo-filling expenses, including labor, equipment charges, etc., made up 49 per cent of the total cost of silage. No doubt this factor had a great deal of influence on the quantity of silage fed during the last three years. A slightly smaller proportion of cattle feeders used silage in the ration during this period, and its use was limited more nearly to roughage requirements than during the feeding seasons of 1918-19 and 1919-20.

The cost of 100 pounds gain depends largely on the prices at which feed, labor, and other items of cost are charged. The cost of gain was lowest in all States during the season of 1921-22, when corn was very cheap. Naturally the highest cost of gain occurred during the first two years of the study. In 1920-21 the feed cost was greatly reduced from that of the previous year but the costs other than feed remained practically the same. During the last two years of the study the costs other than feed were also much lower than they had been during the two years of high prices. In a comparison of the various districts, Figure 7 shows that the cattle fed in the Illinois district had the highest cost of gain during each of the five years. Cattle in the Nebraska and Iowa districts usually ranked lowest in this respect. The charges for feed, labor, and use of equipment were all somewhat higher in the Illinois district than in the other districts.

IMPORTANCE OF VARIOUS ITEMS OF COST

In the fattening of beef cattle, feed is the most important item in the cost of gain. Approximately 84 per cent of the total cost of 100 pounds of gain is made up of feed, 6 per cent is made up of interest on investment in cattle and equipment, 5.5 per cent is labor, and the remaining 4.5 per cent is made up of other costs, such as depreciation of equipment, taxes, veterinary charges, and incidental expenses. These cost relationships change most when the price of feed changes. Thus, feed made up 84 per cent of the total cost of gain during the feeding season ending in the spring of 1919, 86 per cent in 1920, 76 per cent in 1921, and 78 per cent in 1922. Costs other than feed remained about the same or decreased only slightly in 1921 and 1922, but their relative importance increased because the price of corn dropped so noticeably. In 1922–23 the price of corn had increased somewhat over the prices of the two preceding years, and with labor and interest charged at somewhat lower rates feed again made up 84 per cent of the total cost of gain. On the average, 16 per cent of the total cost will cover the charges for labor, equipment, interest, veterinary services, and other costs aside from feed. It should be borne in mind that this is 16 per cent of the total cost and not of the feed cost. The total cost of gain can be roughly calculated by adding 19 per cent of the feed cost to the feed cost.

There seems to be no significant variation in the relation of feed cost to total cost of gain in calves as compared with older cattle. While the cost of gain increases directly with the increase in weight

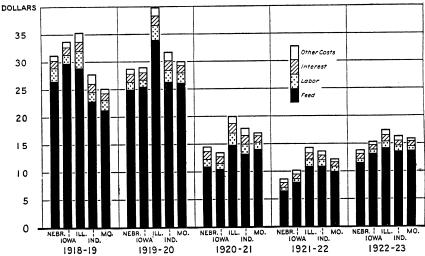

Fig. 7.—FEED-LOT COST PER 100 POUNDS GAIN ON CORN-FED CATTLE, 1919–1923
The cost depends largely upon the price of feed.

of cattle, the different items of cost apparently increase in the same proportion. A heavy steer eats more feed than a calf, requires more labor to feed it, and has a higher interest charge, so that the relation of the items of cost to each other remain approximately the same.

The relation of feed cost to total cost of gain varied considerably in the various districts. In Missouri, Iowa, and Nebraska the relative cost of feed was greater than in Indiana and Illinois. The cost of items other than feed seemed to be mainly responsible for this fact. There was a higher labor cost in connection with the feeding of silage and bundle corn to the cattle in the Indiana and Illinois districts, and the cattle in those districts also had more expensive equipment than the cattle of west-central Missouri, western Iowa, and eastern Nebraska. The higher charges for labor and equipment in the former districts evidently decrease the ratio of the cost of feed to the total cost of gain, in spite of somewhat higher priced feed in those districts.

RETURNS FROM FATTENING BEEF CATTLE IN THE CORN BELT

The financial returns from fattening beef cattle can be expressed in several ways, one of the most common of which is to measure the returns on the per steer basis. In Figure 8 the sale value per steer is compared with the cost of the feeder animal plus the per head costs of feed, labor, interest, equipment, and other costs, for each district, during each year of the study. The value of pork and manure produced behind the cattle has been deducted from the total value of feed to obtain the net feed cost. It will be noticed that the feed cost per head during the last three years was less than half as great as in the first two years, while the original cost of the feeder animal was reduced by about one-fourth. The cattle fed in Illinois and Missouri in

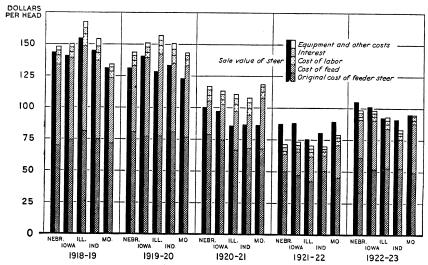

Fig. 8.—Costs and Returns Per Head from Fattening Beef Cattle in the Corn Belt, 1919-1923

The steer-fattening enterprise made greater returns when feed was cheap.

1919-20 and in Illinois, Missouri, and Indiana in 1920-21 were the only groups which did not return the total value of the feed, besides the original cost of the feeder animal, during the years studied. There were many cases, however, especially in 1920-21, where there was no return for labor, interest, use of equipment, and other costs after the feed was aboved at the feeders.

after the feed was charged at the farm price.

Figure 9 illustrates clearly the differences in returns to steer feeders during the five years of study. It is based on the return per \$100 of fattening costs aside from the original cost of the animal. It shows the great losses in 1920–21 and the profits of the last two years. In 1920–21 the average returns from cattle feeding in the different districts ranged from \$37 to \$58 per \$100 worth of feed, labor, and other costs, whereas in the following year the returns ranged from \$118 to \$176 for each \$100 of these costs. Figure 9 shows that cattle in the

Nebraska and Iowa districts did the best; the Illinois cattle returned the least for each unit of cost with the exception of the Missouri cattle in 1920–21. They returned only \$37 for each \$100 of feed-lot costs.

The return for each bushel of corn fed to cattle is often a better measure of income than the returns per \$100 of expenses, when feed is charged at farm prices. This measure of returns as applied to each district under study during the five years is shown in Figure 10. In obtaining the figure for the return per bushel of corn fed, all labor, interest, equipment, and other charges, including the value of all feed other than corn, is deducted from the gross return above the original cost of the feeder animal, and the remainder is divided by the number of bushels of corn fed. For the cattle feeder who feeds his own crop to

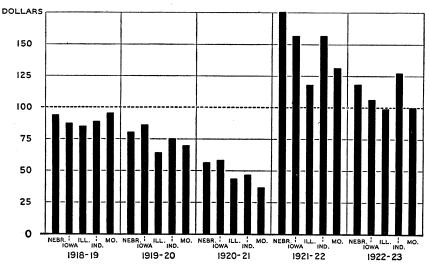

FIG. 9.—RETURNS PER \$100 OF FATTENING COSTS

Fattening costs represent the farmer's feed cost and his labor and equipment charges.

his steers and buys little additional corn, this is a good way to measure the returns from the cattle feeding. It is also a valuable measure of returns when the farm price of corn is changing considerably from year to year. Thus, during the feeding season 1918–19, when the cattle fed in all districts showed a loss with corn charged at farm prices, the return made by cattle for a bushel of corn ranged from \$0.99 to \$1.27. In the winter of 1921–22, however, which was the most profitable year for cattle feeding during this study if corn is charged at farm prices, the return for corn ranged from 63 to 73 cents per bushel. In the same way, when the returns for the seasons 1921–22 and 1922–23 are compared the cattle fed in the latter season did not return quite as much profit per head or per \$100 in costs, but they made a greater return per bushel of corn fed than the cattle fed in the former season.

Although labor and land rentals were higher in 1918 than in 1921, it is no doubt true that the corn for which cattle paid about \$1.15 per bushel in 1918–19 was marketed at a profit if the feeder raised his own corn. On the other hand, the corn which was charged to steers at 40 cents in 1921–22 could probably not have been produced at this cost. The return per bushel of corn fed can be best used where corn makes up the largest part of the feed cost. In the Nebraska and Iowa districts it is very useful in expressing the returns from feeding beef cattle, but in Illinois and Indiana, where a smaller proportion of the corn is fed as grain, and in Missouri, where grass makes up a large percentage of the feed cost, it is not so satisfactory a measure.

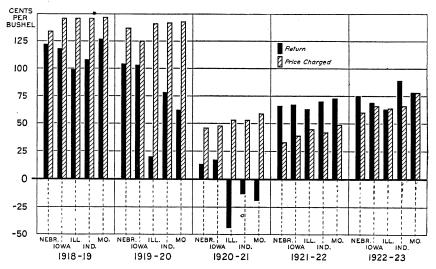

FIG. 10.—RETURN PER BUSHEL OF CORN FED

Feeders who raised their own corn received more for it during the first two years than during the last two years. Individuals might have made still more if they had sold it instead of feeding it.

COMPARISON OF METHODS OF HANDLING AND RATIONS

VARIATION IN RATE AND NET COST OF GAIN

In all tables shown thus far the figures given for the cost and rate of gain have been averages for all the cattle fed in a certain district or in a certain year. In each case there was a rather wide variation in these factors even when the same weight of cattle and the same period of time were considered. Thus, the rate of gain made by heavy steers varied from 0.4 to 4.4 pounds per day, and in the case of medium-weight cattle the variation was from 0.4 to 4.2 pounds per day. The cost of a pound of gain made by medium-weight cattle in 1918–19 ranged from 2 cents to 58 cents, and in 1922–23, when the average cost of a pound of gain was 13.8 cents, the variation in cost was from 6 to 34 cents per pound. (See figs. 11 and 12 for ranges involving 1 per cent or more of the cattle and Tables 30–33 for details and extreme ranges observed.)

These variations in the cost and rate of gain for cattle of the same initial weight and during a given feeding season are largely due to differences in feeding practices, methods of handling, and rations used, but the quality of cattle and the differences in feed prices from district to district are other important reasons for variation.

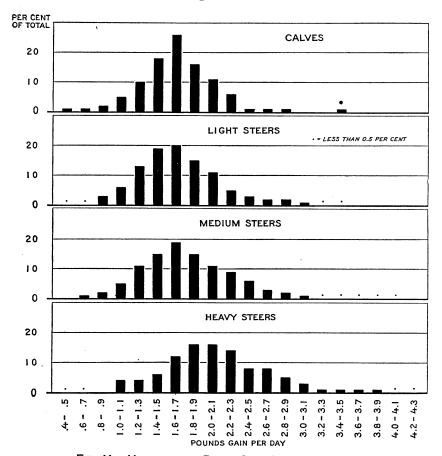

FIG. 11.—VARIATION IN DAILY GAIN MADE PER STEER

Some lots of cattle gain three times as rapidly as others.

The classification of the ordinary methods of handling feeder cattle, as given on page 8, should be remembered in connection with this section of the bulletin.

The differences between these principal methods of handling feeder cattle are shown in Table 8, which gives the basic feed requirements per 100 pounds of gain and per head, together with a few other items for comparison. The initial weight and the rate of gain of the cattle fed in dry lot with practically no pasture were greater, and the length of time on the farm was shorter than for any other group except the

cattle which were purchased in the spring and fed out on the grass. To produce 100 pounds of gain, the dry-lot cattle required more grain,

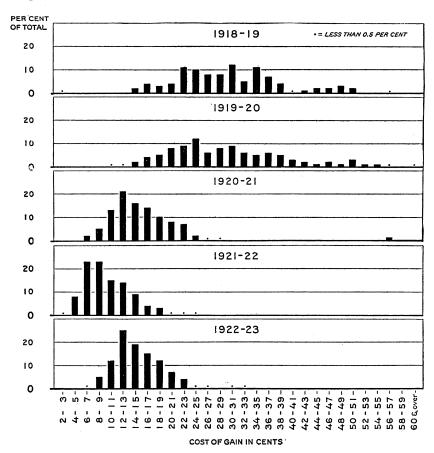

Fig. 12.—Variation in Net Cost per Pound of Gain

The cost of gain even for cattle of the same initial weight varies widely.

silage, and dry roughage than the cattle handled by any other method. The quantity of pork and manure produced per unit of gain was also greatest in the case of the cattle fed in dry lot.

The steers which were wintered and fattened on grass were the only ones that required any more labor per unit of gain than the dry-lot cattle. The fall-pastured steers were slightly lighter in weight when bought, gained a little less rapidly, and remained on the farm 42 days longer than the strictly dry-lot cattle. In producing 100 pounds of gain by this method, 17 days more pasture and a smaller quantity of all other feeds were required than were necessary for the cattle which The 17 days of pasture displaced 58 received practically no pasture. pounds of grain or its equivalent in concentrates, 37 pounds of dry roughage, chiefly legume hay, and 182 pounds of silage. This gives each day of fall pasture a value approximately equal to 3.4 pounds of grain, 2.2 pounds of dry roughage, and 10.7 pounds of silage. Inasmuch as a large share of the fall pasture was second-growth clover or cornstalk pasture which would probably not have been utilized in any other way, it would seem that this method of handling feeder cattle is even more advantageous than it is usually considered. It is especially well adapted to the use of thin cattle. Steers that are in good condition when bought usually gain more rapidly and maintain their finish more readily if turned directly into the feed lot and fed grain than if they are pastured from one to two months on grass or cornstalks. The fall-pastured cattle, together with the strictly dry-lot steers, made up 80 per cent of all the cattle studied.

The summer-pastured steers that were fattened in dry lot during the following winter were lighter in weight when bought and were on the farm longer than were the steers used in any other type of feeding. Only 5 per cent of the cattle studied were handled this way. Because of their lighter weight and their long pasture period they required less grain per unit of gain than any other group under consideration. As a result their credit for pork produced per unit of gain was the lowest of all the groups.

The cattle which were wintered and fattened on grass the following summer were on the farm for eight and one-half months, on the average, and had the lowest rate of gain of any of the five feeding-method groups. The large quantity of straw and stover utilized by these cattle during the winter explains the high labor requirement per unit of gain. This method of handling feeder cattle was very common in Missouri, where 48 per cent of the cattle studied were

handled in that way.

The steers purchased in the spring for fattening on grass were the heaviest cattle when bought and had the highest rate of gain and the shortest feeding period. They naturally used the highest proportion of pasture per unit of gain and a very small quantity of roughage. Silage and hay were fed just before the grass was ready for pasturing in the spring. Their grain requirement was rather high because of their greater original weight and because it is the usual practice to feed grain liberally while the cattle are on grass. The fact that the cattle that were handled by this method were heavier when purchased than those handled by any other method is probably explained by the tendency of older cattle to fatten more easily on grass than do younger steers. All the cattle which were fattened on grass received a considerable quantity of protein concentrates and more prepared feeds and molasses than the cattle finished in dry lot. (Table 8.)

RATIONS USED BY CATTLE FATTENED IN DRY LOT

The rations used in a certain district depend upon the quantity and kind of feed available for cattle feeding. The kind and quantity of feed available depend largely upon climatic and soil conditions. The general farm organization in regard to the number of cattle to be fed, the number of other livestock to be kept, crop rotations, etc., has its influence upon the kind and quantity of feed available for steer feeding and the proportions in which it will be used in the ration. The current prices of farm-grown and purchased feeds also have an effect upon the ration to be used.

Table 9 shows the percentage of droves finished in dry lot that received various rations and feeds. Fifty-eight per cent of all the droves finished in dry lot received a nonsilage ration. In this group the roughage consisted almost entirely of legume and mixed hay.

CORN AND HAY RATIONS FOR BEEF CATTLE

Legume hay has a very important place in the organization of Corn Belt farms, not only from the standpoint of crop rotation and maintenance of soil fertility but because of its value as a feed for live-stock. The ability of beef cattle to utilize this roughage in the fattening ration to good advantage makes it possible for the cattle-feeding enterprise to adjust itself so well to the organization of many Corn Belt forms

Most of the cattle that received a corn and hay ration were fed in eastern Nebraska and western Iowa, where a great deal of alfalfa is grown and where clover hay is plentiful. Alfalfa is an especially dependable source of roughage where good stands can be obtained without undue expense and where soil conditions are well adapted to it. With a sufficient and dependable supply of legume hay available for steer feeding there is little need for a silo. Only 2 per cent of the feeders in the Nebraska district and 17 per cent of the Iowa farmers fed any silage.

The average daily corn and hay ration for 129 droves of cattle ³ weighing 891 pounds when bought was 19 pounds of shelled corn and 9 pounds of legume hay. These cattle gained 2.19 pounds per day for 131 days and required 45 bushels of corn and 1,150 pounds of legume hay per head for the entire feeding period. Each steer fed this simplest of all rations can be credited with 77 pounds of pork.

this simplest of all rations can be credited with 77 pounds of pork.

The importance of legume hay in the western Iowa and eastern Nebraska feeding districts is shown in Table 10, which gives the average daily ration, costs, and returns for the cattle fed in those districts during the period of the study. The small quantity of protein concentrates and prepared feeds used in connection with the corn and legume hay is especially noticeable.

PLACE OF SILAGE IN THE BEEF-CATTLE RATION

Forty-two per cent of all the cattle in this study that were finished in dry lot were fed silage. This percentage varied widely from one district to another, ranging from 85 per cent in Illinois and 81 per cent in Indiana to 2 per cent in the Nebraska district. Over three-fourths of the silage-feeding records were obtained from cattle feeders in Illinois and Indiana. The most important factors which influence the quantity of silage fed to steers in a given locality are (1) the amount of legume hay and other dry roughage available, (2) the price of corn, and (3) the danger of frost damage to immature corn.

The silage rations were divided into two groups—heavy silage and light silage rations. A heavy feed of silage was one of more than 30 pounds per day for heavy cattle, more than 25 pounds per day for medium-weight feeders, more than 20 pounds for yearlings, and more than 15 pounds for calves. The average daily silage consumption for the total number of days on feed was used in making this classification. About twice as many droves received a heavy

silage ration as received a light feed of silage.

Seventy-eight per cent of the silos from which beef cattle were fed, in this study, were of concrete, brick, or tile construction. (Table 41.) The Illinois silos were considerably larger than those found in the Indiana districts. The most common size in Illinois was 14 by 50 feet, whereas in Indiana more of the silos were 12 by 40 feet and 12 by 35 feet than any other sizes. (Table 42.) A typical feed lot where silage feeding is practiced is shown in Plate 1, figure 2.

The average initial cost of building the silos that were filled on these farms during the last three years of this study was \$655. To fill the average silo it was necessary to cut 13.6 acres of corn yielding 47.5 bushels per acre. This made a total of 646 bushels of corn in the silo. The average quantity of fodder put into the silo was 104 tons, or 7.6 tons per acre. This is equivalent to the capacity of a 14-by-38-foot silo in which the silage has settled 5 feet. Since in many of the silos some silage remained from the previous year, the total tonnage fed from the average silo was somewhat more than the quantity mentioned above.

The average length of time required to fill a silo approximately 14 by 40 feet in size was 187 man-hours and 242 horse-hours. This is equivalent to the following crew shown in Table 11 which is typical

of Corn Belt conditions.

Table 11.—Typical Corn Belt silo-filling crew

Operation .	Num- ber of men	Num- ber of horses		Operation	Num- ber of men	Num- ber of hours per unit
Cutting corn with binder Hauling fodder Loading wagons (extra men) _	1 6 2	3 12	20 15 15	Tramping in silo Feeding silage cutter Tending engine	2 1 (¹)	 15 15 (¹)

¹ The engineer was usually hired with the engine.

If all of the labor used in filling the silo had been obtained by exchange with neighbors it would have kept two men and a team busy for two to three weeks. Usually, however, some of the labor was hired by the day or obtained from neighbors who had no silos in exchange for some other kind of work. The time of silo-filling usually came when no other farm work except the preparation of ground for

winter wheat was pressing.

The cost of silage on the farms on which it was fed to beef cattle was obtained for the last four years of the study. For the three seasons, 1920, 1921, and 1922, a detailed analysis of these costs can be made. In determining the cost of silage, charges for labor and equipment and other items used in filling the silo were added to the value of corn in the field. The value of corn in the field was considered to be the farm price of corn minus the cost of husking, plus a nominal charge of about \$1 an acre for the stalks Wherever possible the approximate capacity of the silo was obtained by weighing samples of silage as it was fed to the steers.

The per ton costs of silage for the three feeding seasons 1921–1923 are shown in Table 12. In the average ton of silage there were more than 6 bushels of corn each year. The value of corn made up between 50 and 65 per cent of the total cost of silage. The variation in the ratio of filling costs to total cost of silage may have had some effect on the amount of silage put up during the last three years of this study. The cost of silo filling in the fall of 1920 amounted to \$2.44 per ton. If it is assumed that these filling costs were the same in 1918 and 1919, when no cost data were used (and it is reasonable to suppose that they would not have been any higher in those years), and if corn was

worth about \$1.35 per bushel in the field during those two years, the filling costs would have made up only 23 per cent of the total cost of silage. In 1921 the filling cost had decreased to \$1.95 per ton, but with the price of corn at the low point of 33 cents per bushel it cost practically as much to put the corn in the silo as it was worth in the field.

This does not mean that silage is merely a substitute for corn, for it also displaces a considerable amount of roughage. At the Purdue University Agricultural Experiment Station the average of eight years of feeding trials showed a replacement of 4.6 bushels of corn and 613 pounds of clover hay per ton of silage fed to 2-year-old steers in a ration of shelled corn, cottonseed meal, clover hay, and silage, as compared with a ration of shelled corn, cottonseed meal, and clover hay. The average daily feed consumed by these steers weighing 983 pounds and fed the approved silage ration for an average of 158 days in the feeding trials was as follows: Shelled corn, 13.3 pounds; cottonseed meal, 2.8 pounds; clover hay, 3.2 pounds; and silage, 27.4 pounds.

Tables 13 and 14 give summaries of the results obtained by farmers in Indiana and Illinois when feeding different quantities of silage and when feeding no silage. It will be noticed that farmers did not feed as large a quantity of protein supplement in any of the years as was fed at the experiment station in the experiment cited above. This was no doubt due to the high price of cottonseed meal as compared with corn, especially during the last three years of the study.

Farmers fed considerably more silage per head per day than is usually considered good practice, as indicated by the large proportion of heavy silage records. Aside from the group that fed large quantities of shock corn, they did not feed quite as much grain per day in connection with their silage ration as did the experiment station.

The dry roughage in Indiana consisted principally of corn stover and the quantity of legume hay fed was negligible. In Illinois much more hay was fed especially in the nonsilage ration and a much larger proportion of it was legume hay. The kind and quantity of hay available for feeding cattle is probably the most important factor in determining the place of corn silage and protein supplements in the fatten-

ing ration for beef cattle in the Corn Belt.

In Indiana, the silage-fed cattle of more than 750 pounds initial weight, gained more rapidly than those with a nonsilage ration whose principal roughage was corn stover. In the Illinois district in three out of the four feeding seasons under consideration the steers that received a nonsilage ration consisting principally of shelled corn and legume hay made more rapid gains than those that received either a light or a heavy silage ration. In cost per pound of gain and net returns per head, the corn and hay ration in Illinois and the shock-corn ration in Indiana were more advantageous than the silage rations when charged at farm prices prevailing for feed during the period of study. In both districts, using the heavy silage ration gave a higher cost of gain and a lower net return per head than did using the light silage ration in nearly all instances.

A much larger proportion of the cattle weighing less than 750 pounds when purchased than of the steers that weighed more than 750 pounds was fed silage. In Indiana, 53 out of 57 droves of cattle that weighed less than 750 pounds, and 64 out of 69 droves of like weight in Illinois, received a silage ration. This is evidence of the opinion of feeders that silage is an especially valuable feed for light cattle. A comparison of the rate of gain of lightweight steers fed a heavy silage ration and the rate of gain of those fed a light silage ration showed no consistent difference. For steers weighing over 750 pounds a light silage ration was more advantageous than a heavy

silage ration in cost of gain and net return.

The fact that farmers persist in using a silage ration when these cost figures show, in the same district, a lower cost per pound of gain and higher net return per head if some other ration is used, indicates that all the reasons for the extensive use of a ration can not be explained by limited cost data. Corn silage is a very dependable source of roughage, and in districts where winter-killing, dry summers, and acid soils make the growing of clover hazardous, the use of corn silage is often a necessity to the cattle feeder. In seasons when corn does not mature on account of early frosts or unfavorable weather conditions, the silo is valuable in conserving the grain as well as in changing the stalk into a palatable feed. Even in the average season, when most of the corn matures, the farmer can cut his latest maturing corn and minimize the possible damage from frost.

The organization of the farm influences the quantity of silage used in cattle feeding. As a rule the number of cattle that can be fed for market is limited by the quantity of roughage available. Shelled corn can nearly always be purchased from other farms, but the buying of hay is usually expensive and inconvenient. Hence, the silo has an especially important place on farms where more roughage is needed than can be supplied as hay. A feeder who makes a specialty of feeding cattle in large numbers throughout the year is more likely to use silage than the feeder who handles only 20 to 25 head. The number of cattle per drove in the different districts and the number in the

weight classes is shown in Tables 34 and 35.

Some feeders buy low-grade cattle in the fall, when such cattle are cheap in comparison with other grades and, after giving them a heavy silage ration with little corn, sell them in the spring, when such cattle sell to better advantage than at any other time of the year. Inasmuch as the feeders do not try to get a high finish on these cattle it seems that corn silage might well have an even greater place in the feeding of these low-grade cattle than it has in the feeding of higher

grade steers.

The best time to use the silage in the fattening of beef cattle that are to be highly finished is during the first part of the feeding period, when large quantities of roughage can be used to greatest advantage. During the last half of the feeding period, a full feed of grain should be given in conjunction with the silage in order that a better gain and finish on the cattle may be obtained. In composition, corn silage is deficient in protein; therefore to make the best use of the feed and obtain faster gains and a smoother finish, a protein concentrate should be fed to balance the ration, provided the cost per ton is not so high that the advantage of using it would be questionable.

PLACE OF SHOCK CORN IN THE BEEF-CATTLE RATION

The feeding of shock corn in a strictly dry-lot ration was usual in certain sections of Indiana. It was also rather usual in central Missouri, where a large proportion of the cattle to be fed were carried through the winter to be fattened while on grass the following summer.

The greatest use of shock-corn feeding is found where there is a lack of other roughage. In some districts where there is considerable risk in growing clover, shock corn fills the need for some dry roughage, as a supplement to silage. In other districts where it is possible to grow clover regularly in the rotation, the clover is used principally for pasturing hogs and cattle so that but little hay is available for use in winter feeding. Some feeders, who usually depend upon a corn and hay ration, cut shock corn only when weather conditions have reduced the hay crop. In some cases feeders utilize their silage during the early spring and summer in connection with feeding on grass and use shock corn for roughage during the fall and winter.

Shock-corn feeding also has an important place on farms where considerably more corn is fed to livestock than is produced on the farm. In these cases, which are very common in cattle-feeding communities, it may be necessary to utilize all available hay, silage, and shock corn to furnish the roughage that is necessary when a large

proportion of purchased corn is used.

Another advantage of both shock corn and silage feeding is that the ground can be cleared for seeding winter wheat and a much better seed bed obtained than if the seed were drilled in the standing corn. Following corn with wheat is a common practice in districts where oats are a less profitable crop in the rotation than wheat.

Where shock corn is to be fed almost exclusively it is well to bear in mind that feeders of 800 pounds and over make better use of this feed than do lighter cattle. Its greatest feeding value is realized during the fall and early winter, before it has deteriorated much from weathering. When fed in the feed lot the uneaten stalks make good

bedding and help considerably in keeping the lot dry.

The principal disadvantage of shock-corn feeding is the large amount of labor involved in hauling in the fodder from the field, often in a snowy and frozen condition, and in hauling out the manure containing the long cornstalks. Some farmers have overcome this objection by feeding the shock corn in the pastures or by allowing the stalks to rot before hauling them out of the feed lot.

FATTENING ON GRASS

In the Missouri district, 59 per cent of the cattle fed were fattened while on grass. Less than 8 per cent of the cattle fed in any of the other districts were handled in this way. (Table 5.) About four-fifths of the cattle that were fattened on grass in the Missouri district were bought during the previous fall and carried through the winter on shock corn, hay, corn silage, and stalk pasture. The other one-fifth was bought in the spring and was turned directly out on grass.

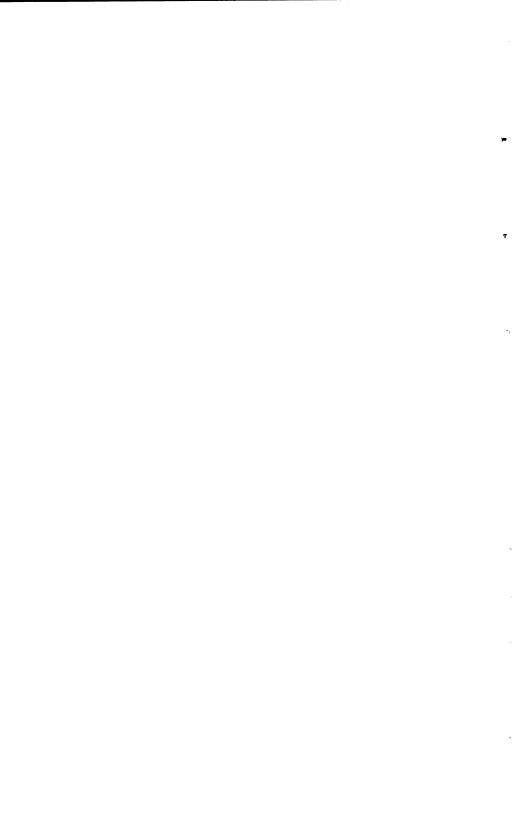

With a large acreage of good pasture and a considerable quantity of corn, it is evident that the Missouri district is well adapted to the fattening of beef cattle. Since most of the feeder cattle come on the market during the fall and can be bought cheaper at that time than in the spring and since a large quantity of cheap roughage is available

FIG. 1.—FATTENING STEERS ON GRASS

FIG. 2.—A DROVE OF FINISHED STEERS OF GOOD QUALITY

in the district, the practice of carrying feeders through the winter to fatten on grass during the following summer has become very common.

(Pl. 2, fig. 1.)

The question naturally arises as to the most desirable weight of feeder cattle to be handled in this way. Calves are too small to be carried through the winter on coarse roughages, and unless they are given a full feed of grain they do not show enough finish to be free from market competition with grass-fat cattle when sold in the late summer or early fall.

Table 15 shows the results of carrying cattle through the winter and feeding them out on grass the next summer. In this table all feeder cattle that weighed over 900 pounds are called heavy, and all those that weighed from 501 to 900 pounds are classified as medium. The table shows that the feeder cattle weighing from 501 to 900 pounds when purchased made a greater daily gain, required less feed per unit of gain, and in all cases made a greater return, per head and per bushel of corn fed, than did the heavier steers. The smaller daily gain and the consequent greater feed requirement per unit of gain, in the cattle weighing over 900 pounds as feeders, is explained by the fact that they already had their growth and any gain that they made had to be made by fattening. Their greater weight at time of purchase was responsible for a part of their greater feed requirement.

Table 15.—Results of feeding heavy and medium-weight cattle that were wintered and fattened on grass the next summer

Inasmuch as the winter ration most commonly used in this district does not often contain enough grain to be very fattening, heavy feeder cattle often go to pasture in the spring weighing very little more than when they were bought in the fall. Lighter cattle, on the other hand, grow out very well when fed on hay or silage and stover with little corn during the winter, and are ready to be fattened with a liberal feed of corn while on grass the following summer. In this way they go to market at a time when there are not many corn-fed cattle leaving the feed lots, and they are sold at a premium above the

price paid for grass-fat cattle without the corn finish.

To have made the same amount of money per head from the heavier steers as from the medium-weight cattle, it would have been necessary to have bought the heavier steers for about 80 cents less per 100 pounds in 1919 and 1920 than was actually paid for them. To have made the same return per head as was made by the medium-weight steers, it would have been necessary to have paid 75 cents per 100 pounds less for the heavier feeders in 1921 and 23 cents per 100 pounds less in 1922 and 1923 than was actually paid for them. The heavy cattle might have made a better showing if they had been fed out with considerable grain in dry lot during the winter over a shorter feeding period, but this study indicates that medium-weight feeders are better adapted to being carried through the winter for fattening on grass than are steers weighing over 900 pounds when bought.

There is considerable variation in the details of the usual system of wintering cattle to be fed out on grass the following summer. Some cattle are "roughed" through the winter very cheaply on stalk pasture, hay, and stover, whereas others receive a substantial grain ration during the winter. There is also a difference in the quantity of grain fed to cattle after they are turned on pasture; some are fed liberally, whereas others receive little or no corn during the pasture period. Although there are several gradations in these two variables—the quantity of corn fed during the winter season and the quantity fed while on pasture—an effort has been made in Table 16 to compare two fairly well-defined methods of wintering and fattening cattle in west-central Missouri. One of these methods consists of roughing the cattle through the winter on cheap roughages and feeding them liberally on grain while on grass the next summer. The other method uses little or no corn while the cattle are on pasture. Cattle handled in this way are called "well wintered."

Table 16.—Results of feeding medium-weight cattle (751 to 1,000 pounds) by different methods, in the Missouri district, in 1922 and 1923

Although these well-wintered cattle received 5 bushels more corn per head during the winter than the cheaply wintered cattle were given during the whole time they were on the farm their rate of gain was slower than that of the steers which were wintered cheaply and received a liberal feed of corn on grass. On this account the cost of gain on the well-wintered cattle was greater, and they required 62 cents more margin ⁴ than the winter-roughed cattle. They actually received a margin of 32 cents per 100 pounds less than the other group. In this case the winter-roughed steers returned 37 cents more per bushel of corn fed to them than did the cattle that received little or no corn during the pasture season.

This would tend to substantiate the claim of many cattle feeders that it is not often advisable to pasture cattle on grass without corn after they have received considerable corn in their winter ration. In certain instances, steers actually lost weight for one or two months after being turned on grass when this practice was followed. It seems, therefore, that it would be more satisfactory to winter the cattle economically with roughages, thus saving the corn for summer feeding on grass, or, after bringing them out of the winter in good shape, to continue the feeding of grain until the cattle are

 $\mathbf{marketed}$.

To determine if this were true four groups of cattle that were fed during the seasons of 1919–20 and 1922–23 are compared in Table 17. One comparison may be made for the first two years of the study, when prices were on a high level, and another for the last two years, when lower prices prevailed. All four groups of cattle, during both periods, were well wintered, with considerable corn and silage in their ration, until the grass was ready for pasturing in the spring. After this time one group received very little or no other feed when on grass, whereas the other group was finished with corn during the whole pasture period.

⁴ Margin is the difference between the purchase price and the sale price, per 100 pounds.

In 1919 and 1920 the group that was given corn while on grass gained 320 pounds per head in 227 days whereas the cattle pastured on grass without corn gained 259 pounds in 254 days. Therefore the cattle that were corn-fed while on grass gained 61 pounds more per head than did the cattle pastured without grain, during a pasture period 27 days shorter than the pasture period of the cattle that were not fed grain. The corn-finished steers were fed 11 bushels more corn per steer than the grass-finished cattle. The quantity of roughage used by the two groups was practically the same although the corn-finished steers received somewhat less silage and received more dry roughage than did the group which was finished on grass with little or no other feed. The feed cost of 100 pounds gain was \$2.06 less for the corn-finished steers at a time when the price of corn was high in comparison with the price of other feeds.

With a greater daily gain and a lower cost per unit of gain, the corn-finished cattle required a margin over the purchase price per 100 pounds, smaller by 77 cents than that necessary for the other group. Actually they sold at a premium of 79 cents per 100 pounds above the margin received by the cattle finished on grass without corn. Expressed in terms of the amount returned per bushel of corn

fed, the corn-finished steers paid \$1.47 for each bushel of corn given to them, whereas those finished on grass alone returned 68 cents per bushel for their winter corn, at a time when the farm price of corn

was \$1.45 per bushel.

The same comparisons may be made with the cattle that were fed during the last two years of the study. With corn cheaper than in 1919 and 1920 it was probably even more important to feed corn to steers that were being fattened on grass. As was the case in the first two years, the steers that received corn during the whole pasture period made a greater daily gain at a lower cost per pound, required a smaller margin over the purchase price per hundredweight, and sold at a margin greater than that received for the steers which were finished on grass alone. The difference in returns amounted to \$12.94 per head.

This study indicates that when cattle have once received considerable corn in their ration, it is more economical to continue the feeding of corn while the cattle are on grass even though corn is relatively high in price. Table 16 indicates that with a limited amount of corn available, it is better to winter the steers as cheaply as possible and save the corn for feeding on grass than to feed them well on grain during the winter and then turn them out to pasture

and give them no more grain.

Another fairly common method of handling cattle that are fattened on grass is to winter them well, then to withhold grain while the grass is good in the spring, and to finish them with a heavy feed of corn during the last few weeks before selling. (Table 18.) The cattle that were fed in this way sold at a wider margin over the purchase price and returned 11 cents more per bushel of corn fed than did the well-wintered steers which received little or no corn on pasture. But the withholding of grain in the spring lowered their rate of gain and thereby increased the cost of gain to the point that they were not nearly so profitable as the steers which were fed corn during the whole pasture period.

On many farms in the Missouri district a considerable quantity of molasses and molasses feeds is ordinarily fed to steers that are being fattened on grass. Table 18 shows that corn and molasses or molasses feed, when fed during the whole pasture period, proved to be almost as profitable as corn alone on grass. The steers that received corn and molasses on grass made slower and more expensive gains, but they brought a wider margin over the purchase price because of an advantage of 98 cents per 100 pounds in sale price. This would indicate a somewhat smoother finish on the molasses-fed steers. The fact that the molasses-fed steers cost 64 cents more per 100 pounds when bought may suggest that they were better quality steers and sold at a higher price for this reason. Feeding experiments indicate that molasses can be used advantageously to replace corn when its price per pound is as low as that of corn.5 Molasses feed mixtures are worth more per pound for feeding cattle than corn when they contain a considerable proportion of concentrated protein and a small proportion of low-grade roughage.

The results of feeding, on Missouri farms, two groups of steers which were bought in the spring and fattened on grass pasture are also shown in Table 18. The small quantity of dry roughage found in their requirements was that fed to some droves which were bought some time before the grass was ready for pasturing in the spring. The medium-weight group was fed more heavily than the large cattle and gained somewhat more rapidly, but neither group made as great a return as did the cattle bought the previous fall. The cattle purchased in the spring gained much faster and probably more economically because pasture made up a larger proportion of their feed cost and because they did not need to be wintered, but their purchase price per pound was higher than that of the cattle purchased in the fall, and their sale price indicates that they were cattle of poor quality or that they were very thin when bought. Although they made

cheaper and more rapid gains, they brought such a narrow margin over the purchase price that they were less profitable than the fall-purchased steers. Unless insufficient feed is available for wintering cattle, it is probably better to buy during the fall a higher grade of steers at a little lower price per pound than can be bought the following spring for fattening on grass.

RESULTS OF FATTENING CATTLE OF DIFFERENT WEIGHTS

Feeders are much interested in the problem of deciding what weight feeder cattle to buy. Although the larger number of the cattle fattened in the Corn Belt weigh between 751 and 1,000 pounds when bought and most of the feeders available for fattening are between these weights, yet the farmer has the choice of buying calves and yearlings that weigh 750 pounds or less or heavy feeders weighing more than 1,000 pounds. The adaptability of various weights of cattle to different rations has already been mentioned. Factors other than rations will now be considered with respect to the way in which they influence the choice of feeder cattle of a certain weight. Among these factors, which vary with the weight of cattle, are the cost and rate of gain, the quantity of feed required per unit of gain, the kind of feed used, purchase price of the feeder animal per 100 pounds and per head, the length of time on the farm, quantity of pork produced, and the returns as influenced by these other factors, together with market conditions at a given time.

One of the most striking differences in the performances of feeder cattle of different weights in the feed lot is in the quantity of feed consumed. The average daily ration of all the heavy steers in this study which received a corn and legume-hay ration in dry-lot feeding was 22.4 pounds of grain and 9.8 pounds of hay. The other classes of cattle that were fed the same ration consumed the following quantities per day: Medium-weight cattle, 19.2 pounds of grain and 8.9 pounds of hay; yearlings, 17.6 pounds of grain and 8 pounds of hay; calves, 13.3 pounds of grain and 6.2 pounds of hay. These figures are typical of the differences in the quantity of feed used daily by steers of different weights when any other ration is considered.

The heavy steers made the greatest average daily gain, but this advantage was not enough to offset the larger quantity of feed consumed per day. This is emphasized in Table 19, which gives the average quantities of feed required per 100 pounds of gain in each district studied. The saving in grain consumed by the lighter-weight cattle as compared with the heavier steers was relatively greater than the saving of roughage. This is also shown in Table 20, in which the feed requirements for the four weight groups of dry-lot cattle are expressed in feed units of concentrates, dry roughage, and silage. To produce a given amount of gain, calves required only 64 per cent as many feed units as did heavy steers. Gain on yearlings was produced with 75 per cent as much feed and on medium-weight feeders with 87 per cent as much feed as was necessary for heavy cattle. The average feed requirement of 92 droves of heavy cattle that were getting a corn and legume-hay ration in dry lot was 9.6 pounds of corn and 4.2 pounds of hay for each pound of gain. Medium-weight cattle that were getting the same ration required 8.8 pounds of grain and 4 pounds of hay to produce a pound of beef. For yearlings, 8.5 pounds of grain and 3.9 pounds of hay were necessary for a pound of gain, and for calves only 7.2 pounds of grain and 3.3 pounds of hay were required to produce a pound of gain.

¹ After due consideration of the analyses of these feeds and of the values given to them in various feeding standards, they were put on a unit basis as follows:

The striking difference in the quantities of feed required to produce 100 pounds of gain on cattle of different weights is also shown in Figure 13. All feeds that were given to cattle handled according to the dry-lot and fall-pasture methods, during the last three years of the study, were reduced to feed units. The increase in the quantity of feed required to produce gain was rather regular except in the

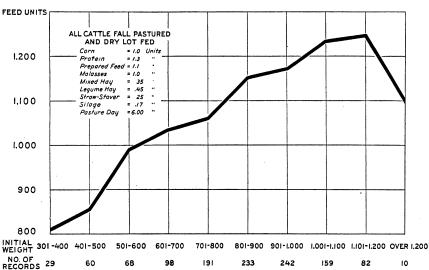

Fig. 13.—Feed Units Per 100 Pounds Gain on Corn-Fed Cattle of Different Weights, 1921-1928

Larger cattle require more feed to put on gain.

case of the cattle weighing over 1,200 pounds when bought. Only a small number of droves were in this class.

It would not be expected that a typical growth curve could be drawn from the feed requirements per unit of gain as found in this study because the feed requirements for growing and for fattening cattle to a given weight are usually different. Moreover, the heavier weights of feeder cattle are usually fed during a short period and, if they are thin when bought, are capable of very rapid daily gains,

which cause their feed requirements per unit of gain to be considerably lower than would be the case if a continous record of their performance since they were calves were available. Heavy cattle may be fattened in a much shorter feeding period than lighter steers because they already have their growth and fatten more easily.

The average length of time that the heavy cattle in the districts studied were on the farm was a little more than four months. Medium-weight cattle were usually on the farm for about six months. The average length of time on the farm for yearlings was almost seven months and for calves a little over seven months. (Table 40.)

On account of the longer feeding period required to fatten light-weight cattle there was less difference in the quantity of feed consumed per head by calves and that consumed by heavy cattle than might be expected. The average quantity of corn per animal for all that received a corn and hay ration in dry lot was 48 bushels for heavy cattle, 49 bushels for medium-weight steers, 47 bushels for yearlings, and 44 bushels for calves. With these quantities of corn, however, the calves put on 329 pounds of gain, while the yearlings gained 298 pounds, the medium-weight cattle 285 pounds, and the heavy steers 262 pounds. The gain which feeders put on calves is ordinarily about 75 pounds greater than the usual gain put on heavy steers.

Although heavy cattle require more feed per day and per unit of gain than do cattle which are lighter in weight, they also have a greater pork credit. The quantity of pork produced behind cattle depends upon the quantity of corn fed, the form in which it is fed, and the size of the cattle. Where ground corn or shelled corn is fed there is less feed for the hogs following steers than where ear corn or fodder corn is given, because there is less waste at the bunk and the corn is more completely digested when fed as ground corn. For light-weight cattle the corn is usually sliced or shelled, but for heavier feeders the ears are only broken. (Table 36.) This explains the smaller quantity of pork produced in feeding the lighter weights of steers.

In this study, heavy and medium-weight cattle had a credit of 31.3 pounds of pork with each 100 pounds of gain as compared with 25.3 pounds for yearlings and 19.2 pounds for calves.

The advantage of heavy cattle in the quantity of pork by-product was not sufficient to offset their greater feed requirement per unit of gain. For all the cattle in this study whose basic ration was corn and hay in dry lot, the quantity of beef and pork produced per bushel of corn fed to cattle was as follows:

Class of cattle	Pounds of beef	Pounds of pork behind cattle	Class of cattle	Pounds of beef	Pounds of pork be- hind cattle
Heavy cattle	5. 45 5. 81	1. 71 1. 82	YearlingsCalves	6. 34 7. 4 7	1. 60 1. 44

The net cost of 100 pounds of gain sums up the advantages of each class of cattle in the quantity of feed consumed, the quantity of pork produced, and the rate of gain. In each year of the study the calves had the lowest cost of gain of any group. Heavy cattle

had the highest cost of gain in each year except in 1919, when 6 of the 13 droves fed were fattened largely on grass in Missouri. The net cost of gain on calves was usually from 65 to 80 per cent of that

on heavy cattle.

The purchase price per 100 pounds of heavy cattle is usually higher than for feeders of any other weight. This is explained by the fact that they are usually in better condition and may be finished within a short feeding period without a very large margin. It should be remembered that the feeder will sell not only the gain which he puts on his cattle but also the initial weight of the animals whose finish he is trying to improve by fattening. Although the cost of gain on heavy cattle is much greater than the cost of gain on calves, their greater original weight makes it possible for them to be fed for a short period without any greater margin over the original cost per hundredweight than is necessary for lighter cattle. If they are fed too long, however, their more expensive gains outweigh this advantage, and they require an ever-increasing margin to pay for their feed and other costs.

During each year of the study, yearlings cost less per 100 pounds when bought than did cattle of any other weight. There are more yearlings on the feeder market than heavy cattle or calves, and they are usually much thinner, often being used as stockers before being fed out. That feeders ordinarily bid more per pound for calves than for yearlings is indicated in Table 21, where the average cost per 100 pounds of feeder cattle of each class is shown for each year.

56944°--27-

The percentage distribution of cattle by weight classes and years according to the

The per head cost and returns in feeding the different weights of cattle are also shown in Table 21. The differences in the original costs per head are striking. The calves cost only about 36 per cent as much per head as did the heavy cattle. The feed and other costs on the per head basis are more nearly equalized because of the longer feeding period of the lighter cattle. Aside from the showing of the heavy cattle in 1919, which is scarcely typical, the returns per head show that heavy cattle made the lowest return in those years when price conditions were unfavorable to cattle feeding and that during the last two years of study, when the price of cattle was rising, they

had a slight advantage over lightweight cattle. In summarizing the advantages of cattle of the various weight classes for fattening in the Corn Belt it should be emphasized that the cost of gain on young cattle is much lower than on older steers because of the smaller quantity of feed required per unit of gain on lightweight feeders. But heavy steers are better able to utilize stalk pasture, corn fodder, and coarse hay than are calves or yearlings, and because they already have their growth they fatten more readily in a short time, whereas calves must be full-fed on grain at least during the last part of their feeding period or they will grow mostly instead of fattening properly. The market demand for heavy cuts of beef is much more limited than for beef from handy-weight steers, hence the price of heavy steers is more sensitive to market demands. Although the greater original weight of heavy cattle makes them much more profitable when the general price trend is upward, their expensive gains and their dependence on a more inelastic demand at the end of a rather definite feeding period make the operation more hazardous than the feeding of younger cattle. With a lower cost of gain on younger cattle, the feeder is not so dependent on market conditions at any one particular time and does not risk so much in waiting for a better market.

IMPORTANCE OF BEEF TYPE IN THE FATTENING OF STEERS

It has been the aim of beef cattle breeders for over a century to produce a better meat animal. Although it is difficult to measure the extent to which beef breeds have been improved, it can safely be said

that the improvement has been considerable.

The ideal beef type desired by breeders and feeders of beef cattle is an animal that will produce the largest proportion of the highest priced cuts of beef when slaughtered. Such a one is necessarily a low-set animal of straight lines, broad and deep bodied, smoothly covered with a thick, even layer of firm flesh. (Pl. 2, fig. 2.) An animal of poor breeding usually deposits its fat around the internal organs instead of interspersing it among the more valuable cuts of lean meat. This type is characterized by such undesirable features as light hind quarters, high flank, narrow thin loin, small heart girth and long, narrow head and neck.

INFLUENCE OF GRADE OF CATTLE ON FEED-LOT PERFORMANCE

To show the effect of quality of feeder cattle on feed-lot performance the personal observation of the field agent was used in dividing the cattle fed in Illinois district in 1922 and 1923 into two groups. One group was made up of steers that were above the average in quality and are here called "good" steers. The cattle that were distinctly below the average in quality are called "common" steers. A comparison of the results of feeding good and common cattle in those years is shown in Table 22.

Table 22.—Results with good and common cattle in the feed lot in Illinois in 1922 and 1923

¹ Above the average.

Good feeder steers always cost more per pound than do common cattle. This fact is accounted for by their performance in the feed lot and at the fat-cattle market. In this instance the common steers cost \$5.13 per 100 pounds original weight, as compared with \$7 per

100 pounds for the good steers.

The good steers gained more rapidly, were more efficient in the use of feed, and at the price at which they were purchased made a greater return for feed, labor, and other charges than did the common steers. A margin of \$1.52 per 100 pounds was needed to break even with good steers, as compared with \$1.99, with common steers. In the net cost of gain the good steers had an advantage of \$2.78 per 100 pounds of gain. To make the same net return per head common steers must be purchased cheaply enough to overcome their handicap in sale price and feed-lot performance.

The feeding of good cattle is not always more profitable than the feeding of common steers because most feeders realize the advantage of good feeder cattle and tend to purchase their cattle at a price at which all grades of cattle will make the same return over a period of

years.

The fact that greater returns are made by feeding common cattle in some years and by feeding good cattle in other years is shown in Table 23, which gives the average profit and loss per head for good and common heavy steers in the Indiana district during the last four years of the study. In two of those years common cattle made the greater return and in the other two years good cattle had the advantage in financial returns,

² Distinctly below the average.

Table 23.—Profit and loss, per head, on heavy cattle of different grades, fed in Indiana

Year	Grade	of cattle	Year	Grade o	of catte
	Good	Common	Icai	Good ·	Common
1919-20 1920-21	-\$29.12 -8.19	-\$13.24 -19.00	1921-22	+\$13.17 +15.15	+\$6.78 +16.54

It may be noticed that the average length of time on the farm of the common steers in Table 22 was 31 days less than for the better cattle. This is probably due to the fact that it is usually considered inadvisable to put a high finish on low-grade steers. Common steers, besides being of a less desirable beef type are usually not as fat when sold as are good steers.

Because of their better use of feed, greater gain per day, and higher sale price when finished, the feeder of the good steers in the years 1922 and 1923 could have paid as much as \$7.73 per 100 pounds for them, while \$5.18 per 100 pounds was the most that could have been paid for the common steers if the feeder were to break even. The actual difference in the purchase price of the two groups was \$1.87 per 100 pounds. These figures indicate that feeders could, in those years, have paid as much as \$2.55 per 100 pounds more for the good feeder steers than for the common ones.

Good steers excel common steers in the feed lot in these particulars: (1) They make greater daily gains, (2) they require less feed per pound of gain, (3) they require less margin between purchase and sale price, and (4) they sell at a higher price per 100 pounds when finished. If feeders judge correctly the differences in price and feedlot performance between good and common steers the returns from feeding the different grades will tend to be the same with seasonal influence duly considered.

SEASONAL VARIATIONS IN PRICE OF BEEF CATTLE OF DIFFERENT GRADES

Since April, 1919, the Bureau of Agricultural Economics has collected prices at the principal livestock markets on four grades of cattle slaughtered. These grades are choice, good, medium, and common. The seasonal variation in the prices of cattle of these different grades is of considerable interest and importance to the cattle feeder in the Corn Belt.

Figures 14 and 15 show that common cattle are generally lowest in price in October and November during the time of large runs of cattle from the range whereas choice cattle are usually higher in price than at any other time of the year because ordinarily very few cornfinished steers are marketed at that time.

Common steers, the thinnest of the four grades, are in demand in the spring for grazing and summer-feeding purposes as well as for the cheaper grades of beef. Consequently the highest prices of the year for common steers are obtained during May, whereas the price of choice steers is lowest in April and May, because most of the cornfinished steers are fattened during the winter and sold in the spring. In this case, however, the price of common steers during May, which was their month of highest prices, was only 79 per cent of that at which choice steers sold during the same period which was their

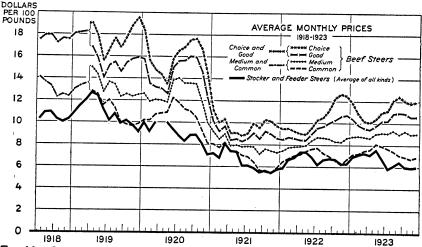

FIG. 14.--AVERAGE MONTHLY PRICES OF DIFFERENT GRADES OF BEEF CATTLE IN CHICAGO, 1918-1923

The seasonal variation in the spread between the price of common and choice beef steers was rather consistent in the five years shown.

month of lowest prices. In November the average price of common steers was as low as 53 per cent of the price of choice cattle. (Table 24.) Another way of expressing the apparent seasonal relationship

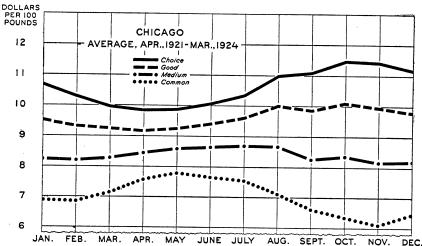

FIG. 15.—SEASONAL VARIATION IN PRICES OF DIFFERENT GRADES OF BEEF CATTLE

Choice beef steers are usually highest during October and November. The highest prices of the year for common beef steers are usually obtained in May and June.

between the price of choice and common steers is to say that during the three years 1921 to 1923 there was an average spread of \$2 per 100 pounds between them during April and May, which increased to \$5 per 100 pounds during October and November.

Table 24.—Seasonal variation in the price relation of different grades of beef cattle, April, 1921, March, 1924

¹Corrected for trend.

The Corn Belt cattle feeder can draw several conclusions from the graphs showing the seasonal variation in the prices of different grades of beef cattle at Chicago from 1919 through 1923. If steers of low quality are to be fattened they should be bought in October or November, when they are relatively low in price, and should be sold in April or May, when there are fewer grass-fat cattle to compete with them on the market and when they usually sell nearest to the price of good and choice steers. It should be remembered, however, that feeder cattle of poor quality gain less rapidly at a greater cost per pound and require a wider margin over the purchase price per 100 pounds than do steers of a better grade. Therefore, they must be purchased cheaply enough to overcome their handicap in feed-lot performance and sale price. The difference in the purchase price necessary to make the same return on good and common steers in 1922 and 1923 amounted to \$2.55 per 100 pounds. (Table 22.)

Many cattle feeders make it a practice to buy good steers weighing over 900 pounds in August or September and finish them for marketing in December or January. Heavy cattle are well adapted to being finished in such a short period, and if they are of good quality they usually sell at a premium over other kinds of cattle at that time of year. There may be more financial risk in feeding heavy steers, but lighter cattle could not be fattened in such a short time. Heavy steers of poor quality should not be handled in this manner without a very wide probable margin because there are usually a large number of range steers still to be marketed as late in the year as December.

Calves and yearlings of good quality that are bought in November may be given a growing ration during the first part of the winter and may be fed out in dry lot for a July or August market to advantage. Hot weather and flies as well as the heavy labor requirement elsewhere on the farm during the crop season are objections to this and

other plans of summer feeding.

Where summer fattening of steers with corn on grass is practiced, Figure 15 would indicate that steers that are somewhat above average in quality should be bought in the fall and wintered over for this purpose. The premium paid for corn-finished steers which grade good or choice from July to October is one of the most important advantages of this type of feeding. Steers that are handled in this way are purchased at the time of year when feeder steers are lowest in price and are sold when the price of corn-fed steers is the highest of the year.

But the majority of the cattle fattened in that part of the Corn Belt where the acreage of pasture is limited will continue to be purchased in the fall, fattened during the winter, and marketed during the spring months because this plan fits in so well with the seasonal nature of marketing from the range and with Corn Belt feed and labor conditions.

MARGINS NECESSARY FOR CATTLE KEPT VARIOUS LENGTHS OF TIME ON GRAIN FEED

Much of the success in fattening cattle on grain depends upon the margin secured on the initial weight of the feeder steer, and on the ability of the cattleman to plan his feeding operations so that he may know the margins necessary to cover costs over each additional week or month of feeding. A knowledge of what another 15 days' or another month's feeding will require in the way of margins to cover costs, considered in the light of probable cattle-price movements, furnishes a basis for choosing the most profitable time for selling. And in the same way, when finished cattle are to be sold upon a certain future market, a knowledge of the margin necessary to cover costs under varying price levels and for different periods on grain feed furnishes a basis for determining the best time and price at which to buy.

In general, as the feeding period is lengthened the rate of gain decreases, the net cost of gain increases, and therefore the margin necessary to cover this cost increases. Table 25 shows the rate at which the margin necessary to cover fattening costs increased as the length of time on grain feed was extended. Table 26 shows the relationship of time on feed to the rate and cost of gain. Of the three factors—rate of gain, cost of gain, and the margin necessary to cover costs, all of which vary as the time on feed varies—the increase in the margin necessary to cover costs followed most closely the increase in the length of the feeding period. This increase in margin required to cover costs was greater for heavy cattle than for cattle of the other weights.

¹ In computing the cost factor for this table uniform prices of corn and silage were used for all groups as follows: In 1919-20, corn at \$1.40 per bushel and silage at \$11 per ton; in 1922-23, corn at \$0.50 per bushel and silage at \$5 per ton.

¹ Per 100 pounds.

In order to show the influence of the length of feeding period on the margin necessary to cover costs, cattle fattened in dry lot and those which were pastured during the fall previous to being finished in dry lot were divided into the usual initial-weight groups and then subdivided according to the length of time that they were given grain feed. days on feed were used as a basis of division instead of the total days on the farm because the cost of gain while on grass alone is usually so low that no margin is required. A difference of 30 days was made for each feeding-period group, beginning with those which were given grain from 50 to 80 days and ending with the longest feeding period of those that were grain-fed for more than 230 days. Thus the feeding periods of the different groups averaged approximately 60, 90, 120, 150, 180, 210, and 240 days.

The purpose in compiling this table was to determine the margin necessary to meet the cost of fattening cattle of different weights and the rate at which this margin increases with the length of time they are on grain feed. When cattle are fattened on grain, the net cost of gain is almost always greater than the sales price per hundred pounds, even when the price of corn is very low. This makes it necessary for the cattle feeder to have a margin over the initial cost per hundredweight to meet all of his expenses. The exceptions to this rule are most common in the case of calves. Fattening cattle on corn improves the quality of beef and hence the selling value of the whole animal. The difference between the purchase and sale price per hundred pounds on the initial weight of the feeder is usually enough to equalize the difference between the net cost of 100 pounds gain and the sale price per hundredweight.

The greater initial weight of the heavy steers makes it possible for them to be fed for short periods of 60 days or less with less margin than medium-weight cattle require. After the first two months, however, their greater cost of gain overbalances the advantage of greater initial weight, and the margin necessary to cover costs widens

more rapidly than for cattle of any other weight.

This was true in 1918-19 and 1919-20, when corn was \$1.40 a bushel, and in 1921–22 and 1922–23, when corn was 50 cents a bushel. Naturally the margin and the increase in margin necessary for the longer feeding periods were much less for cattle of all classes when the price of corn was low. The margin required by calves when corn was high seemed to be greater than that required for the heavier cattle although it increased at a slower rate. If this fact is significant, it would seem that the initial weight of the feeder animal has more effect on the margin necessary to cover feeding costs when cattle and corn are high in price. Although calves gain more economically than older cattle, their fattening costs make up a much larger proportion of the final cost of the animal. When the cost of gain on all cattle is much higher than the sale price per pound, the margin necessary to fatten calves is likely to be wider than the margin necessary for heavy cattle.

The most profitable lengths of feeding period shown in Table 26 are of historical value only. During the high-price period the cattle that were fed for 60 days on grain feed were the only ones that showed a profit. In the last two years the most profitable group of medium and heavy cattle was made up of some that were fed longer than is usually considered good practice. This means only that the price of corn was higher than the price of fat cattle in the first two years and that it was lower in relation to the price of cattle during the last two years. The most that can be said is that it is normally somewhere between these two extremes.

A graph of margins necessary for different lengths of time on feed has been constructed from the available data. (Fig. 16.) The relationship between the margins and days on feed has been represented by a straight line, which seems to fit the data within practical limits. Although figures are available only for the periods when corn was worth \$1.40 and \$0.50 per bushel, an approximation of the margin required to feed corn at \$0.95 a bushel can be obtained by averaging the margin necessary at the other two price levels.

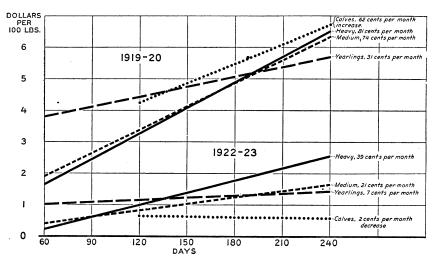

Fig. 16.—Margins Necessary for Different Lengths of Feeding Period with Corn and Hay Rations

The greater weight of heavy cattle makes it possible for them to be fed for short periods with less margin per 100 pounds than is required by lighter cattle.

By means of Table 25 the feeder can tell how much additional margin he needs from month to month to pay the costs on the kind of cattle he is feeding and, with the aid of his knowledge of market conditions, this table will help him to decide when to market his cattle so that they will bring the greatest return for feed. To obtain the price at which steers can be profitably sold at any given time, the marketing expense and the cost of the feeder steer, per 100 pounds delivered to the farm, should be added to the margin given in Table 25. It should be kept in mind that the margin necessary to cover costs is affected by a host of influences, including the prices of cattle, feed, and hogs, the size and quality of cattle, and the suitability of the ration fed. Therefore, the table is at best a rough approximation and should be considered as such.

1 For purposes of closer comparison of the effect of feeding the different rations costs and returns have been recomputed, using the following rates for all droves:

Hogs per 100 pounds	\$15 8
Silage per ton	\$11
Corn per bushel	\$1.40
	Seasons 1919 and 1920

Table 49.—Results of feeding medium-weight cattle typical rations under different systems—Continued

SUMMARY

Cattle feeding in the Corn Belt, besides improving the quality and condition of a large number of cattle coming from the range, tends to equalize the number of cattle slaughtered at different times of the year.

More than half the cattle studied weighed between 751 and 1,000 pounds when purchased as feeders. About one fourth of them weighed from 501 to 750 pounds; the other fourth weighed 500

pounds or less, or more than 1,000 pounds.

The rate and cost of gain on the same kind of steers varied a great deal from one farm to another. The rate of gain on medium-weight steers varied from 0.4 to 4.2 pounds per day, whereas the net cost of gain for cattle of the same weight ranged from 2 to 58 cents per pound in the feeding season of 1918–19 and from 6 to 34 cents per pound in the winter of 1922–23.

Approximately 84 per cent of the total cost of 100 pounds gain was for feed, 6 per cent was for interest on investment in cattle and equipment, 5.5 per cent was for labor, and the remaining 4.5 per cent was made up of other costs such as depreciation of equipment,

taxes, veterinary charges, and incidental expenses.

The value of manure and pork as by-products of cattle feeding was often enough to pay for all costs other than feed. In 1919 the costs other than feed for medium-weight steers finished in dry lot were \$15.07 per steer, whereas the value of manure and pork credited to them was \$15.02 per head. In 1923, costs other than feed amounted to \$7.98 and the pork and manure credit amounted to \$6.86 per steer.

Almost half of the cattle that were finished in dry lot were pastured for some time previous to intensive dry-lot feeding. Each day of fall pasture on second-growth clover or cornstalks was worth 3.4 pounds of grain, plus 2.2 pounds of dry roughage, plus 10.7 pounds of silage, when the feed requirements per 100 pounds of gain on the fall-pastured steers were compared with those of the strictly dry-lot

cattle.

The relative prices of feeds largely determine the proportion in which they should be fed at any given time. In the winter of 1919–20, when corn was \$1.40 per bushel and protein concentrates were \$80 per ton, Illinois farmers fed 537 pounds of grain and 58 pounds of protein concentrates per 100 pounds of gain. In the winter of 1921–22, when corn was 45 cents a bushel and protein concentrates were \$50 a ton, they used 646 pounds of grain and only 14 pounds of protein concentrates per 100 pounds of gain. There was also a saving in the second season of about one-third of the hay and silage used in 1919–20. Steer feeders economized on corn when it was relatively high in price by feeding larger proportions of protein feeds, silage, and hay. When corn was relatively cheap farmers economized on protein feeds, silage, and hay by feeding a larger proportion of corn.

Cattle feeding in eastern Nebraska and western Iowa is typified by the average daily ration of 129 droves of cattle weighing 891 pounds when bought. Each animal received, on an average, 19 pounds of shelled corn and 9 pounds of legume hay and gained 2.19 pounds per day for 131 days. The feed required per head amounted to 45 bushels of corn and 1,150 pounds of legume hay, with a pork

credit of 77 pounds per steer.

Silage feeding is more common in eastern Iowa, Illinois, and Indiana than in western Iowa and Nebraska because of the smaller and more uncertain quantity of legume hay available. In 1920, 1921, and 1922, there was an average of about 6 bushels of corn in a ton of silage. In the same period the average cost of putting the corn in the silo was about \$2 per ton of silage.

Eighty-six per cent of the cattle studied were finished in dry lot, and 14 per cent were fattened while on grass. The practice of fattening while on grass pasture was most common in the west-central Missouri district, where almost two-thirds of the cattle fed were

handled in this way.

Feeder cattle that weigh 900 pounds or less are more desirable to be bought in the fall and carried through the winter to be fattened on grass the following summer than are steers that weigh over 900

pounds when bought.

If cattle are to be finished on grass they should be fed grain during both winter and summer or should be roughed through the winter, and fed grain during the summer pasture period only. This is more profitable than to feed them considerable grain with their roughage during the winter and no grain during the summer-pasture period.

To produce 100 pounds of gain, calves required only 64 per cent as much feed as did heavy cattle. Yearlings and medium-weight cattle required, respectively, 75 and 87 per cent as much feed as

heavy cattle to produce 100 pounds of gain.

Heavy cattle may be fattened in a much shorter feeding period than light-weight steers. A greater cost of gain, together with a more definite date at which they should be finished make the feeding of heavy cattle more hazardous than the feeding of light-weight steers.

Good steers excel common steers in the feed lot in these particulars: (1) They make greater daily gains, (2) they require less feed per pound of gain, (3) they require less margin for an equal length of feeding period between the purchase and sale price, and (4) they sell at a higher price per 100 pounds when finished. To make the same return, common feeders must be bought at a price low enough to offset these advantages of feeding good quality steers. When feeders judge these differences in price and feed-lot performance correctly, the financial returns from feeding good and common cattle tend to be the same, when due consideration is given to the seasonal market influence.

The margin necessary to cover fattening costs increases rather regularly with the length of time on grain feed. When corn was worth about \$1.40 a bushel feeder cattle of medium weight required an additional 75-cent margin to pay feeding costs for every month on feed after 60 days. When corn was worth about 50 cents a bushel, cattle of the same weight needed approximately 20 cents additional margin to cover costs for every 30 days on feed after the first two

months.
